Tidy data structure to support exploration and modeling of temporal-context data

Abstract

Temporal-context data is often rich with information and time formats, for example multiple observational units, different time lengths, heterogeneous data types, nested and crossed factors and etc. This work presents a cohesive and conceptual framework for organizing and manipulating temporal data, which in turn flows into visualization and modelling routines. Tidy data principles are applied and extended to temporal data: (1) mapping the semantics of a dataset into its physical layout, (2) an explicitly declared index variable representing time, (3) a "key" comprised of single or multiple variables to uniquely identify units over time, using a syntatical and user-oriented approach in which it imposes nested or crossed structures on the data. This tidy data representation most naturally supports thinking of operations on the data as building blocks, forming part of a "data pipeline" in time-based context. A sound pipeline practice facilitates a transparent and human readable workflow for analyzing temporal data. Applications are included to illustrate tidy temporal data structure, data pipeline ideas and usage. The architecture of tidy temporal data has been implemented in the R package tsibble.

Keywords: temporal context, time series, data structure, R

1 Introduction

Temporal-context data consist of observational units indexed at different time points X_{jt} , where the j^{th} unit takes measurements of X on over time t, for $j=1,\cdots,N$ and $1 \leq t \leq T$. Time primarily forms the contextual basis of temporal data, but it could arrive in many possible formats. For example, data recorded at fine time resolutions (hours, minutes, and seconds) are typically associated with different time zones and daylight savings. Temporal data often carries with rich information other than the time: multiple observational units of different time lengths, multiple and heterogeneous measured variables, multiple grouping factors involving nested or crossed structures, linking to other data tables, and etc.

In the literature, time series and panel (longitudinal) data are common terms referred to temporal-context data, depending on the research fields. Researchers who are concerned with modelling large T and small N would name as "time series" (serial correlation); those who are interested in modelling small T and large N as "panel data" (asymptotic). The data format is two-dimensional array, but different modelling focuses lend the data input to different representations. A matrix is used to represent multivariate time series where each row represents observations measured at a time point and each column represents a series ("wide" form). This matrix representation requires homogeneity (that is, all the columns must be of same type.), time indices implicitly inferred as attributes or meta-information, series of same time length, and explicit missingness. By contrast, panel data are organised in rectangular form of heterogeneous column types where multiple study subjects are stacked and repeated for its time indices in a single column ("long" form), due to commonly arisen unbalanced panels. This specification requires explicitly declared panel variable and index, which has been implemented in Stata's time series module and R package plm. This data organisation appears more flexible than matrix in supporting explicit time index, multiple subjects of different time lengths, and implicit missing values.

Temporal data can often be aggregated in a manner that exhibits a nested or crossed structure, also known as hierarchical or grouped time series (Hyndman & Athanasopoulos 2017). For example, in a manufacturing setting, a company can add up every store's sales by region, by state and by country, which gives a strictly hierarchical time series; alternatively they can group the sales for each product together based on common attributes such as store, brand, price range and so forth, which leads to a non-hierarchical structure—a grouped time series. The R package hts is the implementation of this type of time series. But it is frustrating to create and work with such data objects due to a machine-oriented interface.

Wickham (2014) formulated the conceptual framework of tidy data: (1) each variable forms a column; (2) each observation forms a row; (3) each type of observational unit forms a table. These principles attempt to standardize the mapping from the semantics of a dataset to its structure and facilitate data analysis in a coherent way. A grammar of data manipulation.

This paper proposes a unified data representation of temporal-context data, by leveraging the "tidy data" principles. Built on a two-dimensional array of long format, observations and variables find and bridge their meanings in both physical and underlying representations.

This paper proposes a unified data representation and a modern data pipeline for storing,

managing and analysing time series data, using a collection of fluent and fluid tools to help with

exploitation in temporal context.

2 Data semantics

A modern re-imagining of time series should provide heterogeneous data types and time indices

as explicitly declared data column. This can be achieved using a "data frame" in R or other

statistical languages to represent a tabular format, instead of "matrix". Tidy temporal-context

data at least consists of:

1. index: an explicitly declared data variable contains time indices, such as date-times,

year-months, years and etc.

2. key: a set of grouping factors uniquely identifies each unit that measurements take place

on over time, which may include single or multiple columns.

3. interval: data with regular time interval results in a common time interval in one table.

In SQL database, a primary key (Codd 1970), which uniquely defines each record in a database,

is equivalent to the composition of "index" and "key".

2.1 Time index and interval

Time index forms an integral component and contextual base of temporal data. In temporal

data frame, time-based index must be clearly stated as a data column rather than inferred as

attributes, and thus can be accessible. This creates flexibility in handling time indices.

(1) temporal elements can be created, and then exploratory data visualisation and analysis

(not specialist plotting) and multiple seasonality modelling for sub-daily data

(2) convert to the same time zone and thus compare

(3) join other data tables using the index as common key

For data indexed in regular time space, the time interval is obtained by computing the minimal

positive time distance in a data table. This suggests that each observational unit collected at the

same interval forms a table.

2.2 Keys

Key variables are usually discrete descriptors, and are typically variables that were created during the data collection to uniquely define the measured values. For instance, to distinguish the performance of each flight in the dataset, the "key" is the flight variable, allowing separation of multiple time series in one data table. The "key" not only identifies the unit to be measured over time, but also incorporates structures of data. Without a key, a data table can be considered as a univariate time series; in other words, the key is implicit. With a single key of more than one categories, it lends itself to a collection of time series in a table. But when there are at least two keys in the table, it indicates nested or crossed structures.

In experimental designs, a variable is crossed with another when every category of one variable co-occurs with every category of the other, while a variable is nested within another when each category of the former variable co-occurs with only one category of the latter. It appears more useful in making this distinction in statistical analysis including visualisation and modeling, compared to data manipulation.

3 Data pipeline

Tidy data builds a concrete foundation to enable pipeline data analysis, which provides a coherent and fluent framework to work with data. It helps (1) break up a big problem to into manageable blocks, (2) generate human readable analysis workflow, (3) avoid introducing mistakes as many as possible.

```
• row-wise: filter(), slice(), arrange(), fill_na()
```

• column-wise: mutate(), select(), summarise(), tsummarise()

• rolling window: slide(), tile(), stretch()

• statistics: lag(), diff(), acf()

4 Application: U.S.A domestic flights on-time performance (2016-2017)

A dataset of on-time performance of domestic flights in U.S.A from 2016 to 2017 is studied and explored for illustration of tidy data and data pipeline.

5 Discussion

A tidy representation of time series data, and data pipelines to facilitate data analysis flow have been proposed and discussed. It can be noted that tidy temporal data gains greater flexibility in keeping data richness, making data transformation and visualisation easily. A set of verbs provides a fluent and fluid pipeline to work with tidy time series data in various ways.

The ground of time series modelling or forecasting is left untouched in this paper. The future plan is to bridge the gap between tidy data and model building. Currently, it is required to casting to matrix from tidy data and therefore building a model. But time series models should be directly applied to tidy data as other wrangling tools do, without such an intermediate step. In particular, a univariate time series model, like arima and exponential smoothing, can be applied to multiple time series independently. A tidy format to represent model summaries and forecasting objects will be developed and implemented in the future. Model summaries include coefficients, fitted values, and residuals; forecasting objects include future time path and distributions generating prediction intervals.
